STAT347: Generalized Linear Models Lecture 8

Today's topics: Chapter 6.2-6.3

- Ordinal response models
- Examples of multinomial GLM

1 Ordinal response

Say the response (disease status of the sample) is one of these 4 categories: healthy, mild, moderate, severe. How do we build a model to predict the response / understand the covariates' effect?

- The categories have an order
- One naive solution: ignore the categorical nature of y
 - Encode $y_i = 1, 2, 3, 4$ as a score for healthy, mild, moderate, severe. Build a linear regression model

$$y_i = X_i^T \beta + \epsilon_i$$

- Usually no clear-cut choice for the scores
- A more detailed comparison between this OLS and the model we will introduce later

1.1 Cumulative logit/probit models: latent variable motivation

Denote $y_i = k$ if the response is in the kth ordered category. Assume that there is a continuous latent variable for each sample y_i^* that satisfy

$$y_i^* = X_i^T \beta + \epsilon_i$$

where ϵ_i are i.i.d. with the cdf function $F(\cdot)$. Suppose that there are some cutpoints

$$-\infty = \alpha_0 \le \alpha_1 \le \dots \le \alpha_c = \infty$$

such that we observe

$$y_i = k$$
 if $\alpha_{k-1} < y_i^* \le \alpha_k$

Then, we have

$$P(y_i \le k) = P(y_i^* \le \alpha_k) = F(\alpha_k - X_i^T \beta)$$

When we take F as the cdf of standard logistic/Gaussian distribution, we get the cumulative logit/probit models.

- For identifiability, X_i here does not include the intercept term
- We assume constant β across categories

Another equivalent way to define the cumulative logit model

$$\operatorname{logit}[\mathbb{P}(y_i \le k)] = \log \frac{p_{i1} + \dots + p_{ik}}{p_{i,k+1} + \dots + p_{ic}} = \alpha_k + X_i^T \beta$$

1.2 Fitting cumulative link models

We assume that $P(y_i \leq k) = F(\alpha_j + X_i^T \beta)$, then the likelihood for ungrouped data is

$$\prod_{i=1}^{N} \left(\prod_{k=1}^{c} p_{ik}^{y_{ik}} \right) = \prod_{i=1}^{N} \left\{ \prod_{k=1}^{c} [P(y_i \le k) - P(y_i \le k - 1)]^{y_{ik}} \right\}$$

The log-likelihood is

$$L(\alpha,\beta) = \sum_{i=1}^{N} \sum_{k=1}^{c} y_{ik} \log[F(\alpha_k + X_i^T \beta) - F(\alpha_{k-1} + X_i^T \beta)]$$

and the score equation for β_j is

$$\frac{\partial L}{\partial \beta_j} = \sum_{i=1}^N \sum_{k=1}^c y_{ik} x_{ij} \frac{f(\alpha_k + X_i^T \beta) - f(\alpha_{k-1} + X_i^T \beta)}{F(\alpha_k + X_i^T \beta) - F(\alpha_{k-1} + X_i^T \beta)} = 0$$

for α_k is

$$\frac{\partial L}{\partial \alpha_k} = \sum_{i=1}^N \left\{ \frac{y_{ik} f(\alpha_k + X_i^T \beta)}{F(\alpha_k + X_i^T \beta) - F(\alpha_{k-1} + X_i^T \beta)} - \frac{y_{i,k+1} f(\alpha_k + X_i^T \beta)}{F(\alpha_{k+1} + X_i^T \beta) - F(\alpha_k + X_i^T \beta)} \right\} = 0$$

The computation is complicated, but we can still use Fisher-scoring/Newton's method to solve it and we can still calculate the asymptotic variances of β and each α_k .

1.3 Comparison with OLS

Limitation of the cumulative link models:

- Settings are stochastically ordered If $X_i^T \beta \ge X_{i'}^T \beta$ then we have $P(y_i \le k) \ge P(y_{i'} \le k)$ for ALL k.
- When c = 4, the model can not allow the probability of each ordered category to be (0.3, 0.2, 0.2, 0.3) for one sample and (0.1, 0.4, 0.4, 0.1) for the other sample.
- Read Chapter 6.2.4 for how to build more flexible models under this scenario

Disadvantages of modeling ordered categories using a lienar model:

- Usually no clear cut for the numerical scores
- Linear model does not allow for the measurment error is discretization
- From the linear model you can not get estimated probabilities of each category for a particular sample
- Linear model ignores that the variability in each category can be different

(Read Chapter 6.2.5)

A simulation example (Figure 6.3)

$$y_i^* = 20 + 0.6x_i - 40z_i + \epsilon_i$$

where $x_i \stackrel{i.i.d.}{\sim}$ Uniform[0, 100], $z_i \stackrel{i.i.d.}{\sim}$ Bernoulli(0.5) and $\epsilon_i \stackrel{i.i.d.}{\sim} N(0, 10)$. Set $\alpha_1 = 20$, $\alpha_2 = 40$, $\alpha_3 = 60$ and $\alpha_4 = 80$.
